1 Introduction

1.1 Classical Motivation: Newton's Method

Newton's method (also called Newton-Raphson) is an algorithm for finding roots of a polynomial. If $p(z)$ is a polynomial, then we construct the auxiliary function $f(z) = z - \frac{p(z)}{p'(z)}$. We then pick some value z_0 and we iterate, so that $z_{i+1} = f(z_i)$. Sometimes, depending on p and z_0 , this sequence converges to some z , so that $z = z - \frac{p(z)}{p'(z)}$, i.e. $p(z) = 0$. We can view this graphically for real values of z as follows:

Figure 1: Newton's method for $p(z) = z^3 - 1$

It's not too hard to see that, no matter our starting choice of z_0 , this process will always eventually converge towards $z = 1$, and that $p(1) = 0$.

If instead we consider this iteration for **complex** values of z_0 , we might converge to different roots of $p(z)$, since p also has two complex roots. It turns out that the question of deciding which root we will converge to is not easy, and in fact we can see which root will be converged to in the following convergence diagram¹

¹Courtesy of usefuljs.net/fractals/docs/newtonian_fractals.html

Figure 2: Convergence diagram for $z^3 - 1$

We have many different stable behaviours of this dynamical system, but the boundary is very chaotic. For example, if we consider $p(z) = z^4 - 2z^2 + 9$, note that if $z \in \mathbb{R}$, then $f(z) \in \mathbb{R}$. However, the four roots of p are all complex, and so Newton's method will fail to work for $z_0 \in \mathbb{R}$, and this can be seen in the following image:

Figure 3: Convergence diagram for $z^4 - 2z^2 + 9$

1.2 Applications Motivation: Fixed Point Problems

Gravitational Lensing: Suppose we have n point masses in a plane perpendicular to the line of sight, and we are observing an object at the origin of this plane, identified with the complex plane. Call the points z_1, \dots, z_n , with masses $\sigma_1, \dots, \sigma_n$ respectively. Then the images of the object at the origin are the solutions to the *lens equation* $z = \sum_{j=1}^n \frac{\sigma_j}{\bar{z} - \bar{z}_j}$. We see this for instance in the following image, courtesy of Nasa

Figure 4: The same galaxy appearing 3 times in an image captured by Hubble.

For example, if we have a point mass at the origin $n = 1, z_1 = 0$. The lens equation gives us images of it at $z = \frac{\sigma_1}{z}$, i.e. $|z|^2 = \sigma_1$. The solution is a circle, known as an *Einstein ring*.

Figure 5: An Einstein ring, captured by Hubble.

In general, we might want to ask how many images we will see for a give configuration, or perhaps a given number, of point masses.

Define $r(z) := \sum_{j=1}^n \frac{\sigma_j}{z-z_j}$, and we are looking for solutions to $z = \overline{r(z)}$, i.e. fixed points of the (non-meromorphic) function $z \mapsto \overline{r(z)}$. These will be among the solutions of the (meromorphic) function $z \mapsto \overline{r(\overline{r(z)})} = r(r(z))$, of degree n^2 . One can show that it suffices to bound the number of *attracting* fixed points, which will be done in one of the main theorems of this course:

Theorem 1.1. *Let $f(z)$ be a rational map of degree $d \geq 2$. Then f has at most $2d - 2$ attracting fixed points.*

There are still open questions related to this application; for example, the following conjecture is still open despite its simplicity:

Conjecture 1.2 ((Lee, Lerario, Lundberg)). *If p is a polynomial of degree n , q a polynomial of degree m , and $n > m$, then the number of solutions to $p(z) = \overline{q(z)}$ is bounded above by $2m(n - 1) + n$.*

1.3 Where We're Heading

Define $f_c(z) := z^2 + c$, where $c \in \mathbb{C}$. **The Mandelbrot Set** $M := \{c \in \mathbb{C} : |f_c^n(0)| \not\rightarrow \infty \text{ as } n \rightarrow \infty\}$.

Figure 6: The Mandelbrot set, generated by me.

2 Complex Basics

2.1 The Riemann Sphere

The *Riemann Sphere* $\widehat{\mathbb{C}}$ is the one-point compactification of \mathbb{C} , given by adding a point at ∞ . The basis of this topology around ∞ are the complements of the closed discs in \mathbb{C} .

Definition 2.1. A **domain** in the Riemann sphere is any open connected subset of $\widehat{\mathbb{C}}$.

We can then think about *maps of the Riemann sphere*, which are rational maps of the form $f(z) = \frac{p(z)}{q(z)}$, where p, q are polynomials with no common roots. We define the *degree* of f to be the maximum of $\deg p, \deg q$.

Definition 2.2. We say that $f : \widehat{\mathbb{C}} \rightarrow \widehat{\mathbb{C}}$ is **holomorphic at ∞** if $f(1/z)$ is meromorphic on a neighbourhood of 0.

Lemma 2.3 (Identity Principle). Let $f : D \rightarrow D$ be a holomorphic, non-constant map on a domain D in $\widehat{\mathbb{C}}$. Then for any $w \in D$, $f^{-1}(w)$ is discrete. In particular, if $D = \widehat{\mathbb{C}}$, then $f^{-1}(w)$ is finite.

Proof. First, composing with a Möbius map, we may assume $w = 0$. By the principle of isolated zeros, $\forall z \in \widehat{\mathbb{C}}$, there is some disc $D_z \ni z$ such that either $f \equiv 0$ on D_z or f is nonzero on $D_z \setminus \{z\}$.

Let $V := \bigcup_{f=0 \text{ on } D_z} D_z$, $W := \bigcup_{f \neq 0 \text{ on } D_z} D_z$

Then $V \cup W = D$, these sets are open, and $V \cap W = \emptyset$. Since D is connected, V and W cannot disconnect D , so one of V and W is empty. f is nonconstant, so $V = \emptyset$, and so the zeros are discrete. As $\widehat{\mathbb{C}}$ is compact, any discrete subset is finite. \square

Proposition 2.4. Let $f : \widehat{\mathbb{C}} \rightarrow \widehat{\mathbb{C}}$ be a holomorphic, non-constant map. Then f is a non-constant rational function; that is, there exist $a_1, \dots, a_m, b_1, \dots, b_n \in \mathbb{C}$, and $c \in \mathbb{C}^\times$ such that:

$$f(z) = \frac{c(z - a_1) \dots (z - a_m)}{(z - b_1) \dots (z - b_n)}$$

Proof. Replace by $\frac{1}{f}$ if necessary to assume $f(\infty) \in \mathbb{C}$. By the identity principle, $f^{-1}(\infty)$ is a finite subset of $\widehat{\mathbb{C}}$. Call it $\{b_1, \dots, b_n\}$. Near each b_j , we have a local expansion of f as $f(z) = \sum_{i=-k}^{\infty} a_{j,i}(z - b_j)^i$. Set $Q_j(z) = \sum_{i=-k}^{-1} a_{j,i}(z - b_j)^i$, each Q_j is a rational function and $g := f - (Q_1 + \dots + Q_n)$ has only removable singularities. So $g(\widehat{\mathbb{C}}) \subseteq \mathbb{C}$. Since $\widehat{\mathbb{C}}$ is compact, $g(\widehat{\mathbb{C}})$ is a compact, proper, open subset of $\mathbb{C} \setminus \{0\}$ (by Heine-Borel). Therefore g is constant, and f is rational. \square

2.2 The Derivative at Infinity

Caution: there is not a globally well defined notion of a derivative of $f : \widehat{\mathbb{C}} \rightarrow \widehat{\mathbb{C}}$, since we can change coordinates in many different ways. However, if $f(\infty) = \infty$, then we do, as the local derivative is independent of choice of coordinates. In this case, we define $f'(\infty)$ to be the derivative at 0 of $\frac{1}{f(1/z)}$.

2.3 Uniformizations

We say a group Γ acts *properly discontinuously* on a set if all points p have a neighbourhood $N \ni p$ with $g(N) \cap h(N) = \emptyset$ for all $g \neq h \in \Gamma$

Theorem 2.5 (Uniformization in $\widehat{\mathbb{C}}$). Let U be a domain in $\widehat{\mathbb{C}}$. Then the universal cover \widetilde{U} of U is either $\widehat{\mathbb{C}}$, \mathbb{C} , or \mathbb{D} , and $U \simeq \widetilde{U}/\Gamma$ for some subgroup $\Gamma \leq \text{Aut}(\widetilde{U})$ which acts properly discontinuously.

We now consider the different cases:

- Universal Cover $\widehat{\mathbb{C}}$: $\text{Aut}(\widehat{\mathbb{C}}) = \{\text{Möbius transformations}\}$

All Möbius transformations have at least one fixed point. So if Γ acts properly discontinuously on $\widehat{\mathbb{C}}$, Γ must be $\{\text{id}\}$, and as such $U = \widetilde{U} = \widehat{\mathbb{C}}$.

- Universal Cover \mathbb{C} : $\text{Aut}(\mathbb{C}) = \{\text{Möbius transformations fixing } \infty\}$

These transformations are the linear maps, i.e. $f(z) = az + b, a \neq 0$. If a non-identity map lies in Γ , then it has no fixed point, and hence $az + b = z$ has no solutions, i.e. $a = 1, b \neq 0$. So Γ consists of the translations, and we can identify $g \in \Gamma$ with $g(0) \in \mathbb{C}$.

$\Gamma \leq \mathbb{C}$ consists of isolated points, so $\Gamma = \{\text{id}\}, \langle \omega \rangle$ for some $\omega \in \mathbb{C}$, or a lattice Λ .

These correspond respectively to $U \simeq \mathbb{C}, U \simeq \mathbb{C}^\times$, and a complex torus (which is not a subdomain of \mathbb{C}).

- Universal Cover \mathbb{D} : $\text{Aut}(\mathbb{D}) = \{e^{i\theta} \frac{z - \omega}{1 - \bar{\omega}z} : \theta \in \mathbb{R}, \omega \in \mathbb{D}\}$.

All the rest! Any domain which omits at least three points of $\widehat{\mathbb{C}}$ has the disc as its universal cover. This gives a lot of different subgroups of $\text{Aut}(\mathbb{D})$ - we won't study which ones are possible in this course.

Definition 2.6. We say a domain $U \subseteq \widehat{\mathbb{C}}$ is **hyperbolic** if it has universal cover \mathbb{D} , or equivalently if it omits at least 3 points.

If U is a hyperbolic domain, then the covering maps $\widetilde{U} \rightarrow U$ are holomorphic. So if $f : U \rightarrow V$ is a holomorphic map between hyperbolic domains, then its lifted map g is also holomorphic. g is also unique up to a choice of an element of Γ_V

Theorem 2.7 (Picard Theorem). *If U is a hyperbolic domain, and $f : \mathbb{C} \rightarrow U$ is holomorphic, then f is constant.*

Proof. The following diagram commutes:

$$\begin{array}{ccc} \mathbb{C} & \xrightarrow{g} & \mathbb{D} \\ \downarrow \text{id} & & \downarrow \pi_U \\ \mathbb{C} & \xrightarrow{f} & U \end{array}$$

So g is a holomorphic function from \mathbb{C} to \mathbb{D} , so bounded, so constant by Liouville's theorem. Hence f must also be constant. \square

In fact, there are no non-constant holomorphic maps from $\widehat{\mathbb{C}}, \mathbb{C}, \mathbb{C}^*$ to any hyperbolic domain.

Recall that the hyperbolic (or Poincaré) distance between any two points on the disc is the infimum along smooth curves $\gamma : [a, b] \rightarrow \mathbb{D}$ which connect the two points of the length value:

$$\ell(\gamma) = \int_a^b \frac{2}{1 - |\gamma'(t)|^2} |\gamma'(t)| dt$$

Using the origin and automorphisms, one computes that the distance function is given by

$$d(x, y) = \frac{\log(1 + R)}{\log(1 - R)}$$

where $R = \left| \frac{y-x}{1-\bar{x}y} \right|$.

Definition 2.8 (Hyperbolic/Poincaré metric of a hyperbolic domain). *Taking the covering map $\pi : \mathbb{D} \rightarrow U$ for U a hyperbolic domain to be a local isometry, we define a unique metric on U known as the hyperbolic/Poincaré metric on U .*

Theorem 2.9 (Pick Theorem). *The $f : U \rightarrow V$ be a holomorphic map of hyperbolic domains $U, V \subset \widehat{\mathbb{C}}$ with Poincaré metrics ρ_U, ρ_V respectively. Then for all $x, y \in U$:*

$$\rho_V(f(x), f(y)) \leq \rho_U(x, y)$$

with strict inequality unless f lifts to an automorphism of \mathbb{D} .

Proof. By definition of ρ_U, ρ_V , it suffices to prove this for $f : \mathbb{D} \rightarrow \mathbb{D}$. We want to show that

$$\frac{\log(1 + R')}{\log(1 - R')} \leq \frac{\log(1 + R)}{\log(1 - R)}$$

where

$$R = \left| \frac{y - x}{1 - \bar{x}y} \right|, \quad R' = \left| \frac{f(y) - f(x)}{1 - \overline{f(x)}f(y)} \right|$$

As $\frac{\log(1+x)}{\log(1-x)}$ is strictly increasing, it is sufficient to show $R' \leq R$. Define:

$$\sigma_1(z) = \frac{y - z}{1 - \bar{y}z}, \quad \sigma_2(z) = \frac{f(y) - f(z)}{1 - \overline{f(y)}f(z)}$$

Then $\sigma_2 \circ f \circ \sigma_1^{-1} : \mathbb{D} \rightarrow \mathbb{D}$ fixes 0. So by Schwarz's lemma, $|\sigma_2 \circ f \circ \sigma_1^{-1}(z)| \leq |z|$, i.e.

$$\left| \frac{f(y) - f(x)}{1 - \overline{f(y)}f(x)} \right| \leq \left| \frac{y - x}{1 - \bar{y}x} \right|$$

by setting $\sigma_1^{-1}(z) = x$. The statement with strict inequality follows similarly. \square

Thus all maps of hyperbolic domains are (weakly) contracting with respect to the hyperbolic metric. This is in contrast to the non-hyperbolic case, where we can have things like $f : \mathbb{C} \rightarrow \mathbb{C}, z \mapsto 2z$ which is expanding, or $g : \widehat{\mathbb{C}} \rightarrow \widehat{\mathbb{C}}, z \mapsto z + 1$, which has expansion and contraction at the same time in different regions.

3 What is a reasonable notion of stable/predictable behaviour under iteration?

For example, take $f(z) = z^2$, so that $f^n(z) = z^{2^n}$. If $|z| > 1$, then $|f^n(z)| = |z|^{2^n} \rightarrow \infty$. On the other hand, if we start with a point inside the unit disc, then $|f^n(z)| \rightarrow 0$. This is a stable property - if z goes off to ∞ or 0 under iteration of f , then $z + \varepsilon$ for $|\varepsilon|$ small also goes off towards ∞ or 0 respectively.

In contrast, if $|z| = 1$, then we do not have this stable behaviour.

Definition 3.1. Let S, T be metric spaces and $f_n : S \rightarrow T$ a sequence of continuous maps. We say that $\{f_n\}$ **converges locally uniformly** if for all compact $K \subset S$ and all $\varepsilon > 0$ there exists $N \in \mathbb{N}$ such that

$$\sup_{z \in K} d_T(f_n(z), f_m(z)) < \varepsilon$$

for all $n, m \geq N$.

We say that $\{f_n\}$ **diverges locally uniformly** if for all compact $K \subset S$ and compact $K' \subset T$, we have $N \in \mathbb{N}$ such that $f_n(K) \cap K' = \emptyset$ for all $n \geq N$.

Example: Let $p(z) = a_d z^d + \dots + a_0 \in \mathbb{C}[z]$ a polynomial, with sequence of iterates $\{p^n(z) : n \in \mathbb{N}\}$. If $|z| \gg \max\{|a_d|, \dots, |a_0|\}$, then $|p(z)| \approx |a_d z^d|$. So $|p^n(z)| \rightarrow \infty$ as $n \rightarrow \infty$. Considering $p : \widehat{\mathbb{C}} \rightarrow \widehat{\mathbb{C}}$, the sequence $\{p^n(z)\}$ converges locally uniformly on a neighbourhood of ∞ .

Note that the definition of S, T matter - if we consider $p : \mathbb{C} \rightarrow \mathbb{C}$ instead then the sequence of iterates $\{p^n(z)\}$ diverges locally uniformly on the complement of some large disc.

Definition 3.2. A family \mathcal{F} of continuous functions $f : S \rightarrow T$ is **normal** if every sequence in \mathcal{F} has a subsequence which is either locally uniformly convergent or locally uniformly divergent.

Lemma 3.3. Let U, V be domains and \mathcal{F} a normal family of holomorphic maps $U \rightarrow V$. Then any sequence $\{f_n\}$ in \mathcal{F} has a subsequence which converges to a holomorphic limit $g : U \rightarrow \bar{V}$, where \bar{V} is the closure of V in the Riemann sphere.

Proof. \mathcal{F} is normal, so pass to a subsequence of holomorphic maps to assume locally uniform convergence or divergence.

If $\{f_n\}$ converges locally uniformly, then \bar{V} compact implies we have a limit function $g : U \rightarrow \bar{V}$, by taking $K = \{\text{pt}\}$ in the definition. By the Weierstrass uniform convergence theorem, this is holomorphic.

If $\{f_n\}$ diverges locally uniformly, then for any compact $K \subset U$, we have some convergent subsequence $f_{n_k}(z) \rightarrow z_0 \in \partial V$ for any choice of $z \in K$. If U, V are hyperbolic, then by Pick's theorem, all elements of K converge to z_0 , and so we have local uniform convergence to the constant function at z_0 . If U, V are not hyperbolic, we may shrink U slightly to still contain K , but be hyperbolic U_0 with compact closure in U . By local divergence, we can remove points from V and initial elements of the sequence $\{f_n\}$ to assume V is hyperbolic. \square

Example: $f(z) = z^2$. $\mathcal{F} := \{f^n(z) : n \in \mathbb{N}\}$.

$\widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}$ is a hyperbolic domain, and $f : \widehat{\mathbb{C}} \setminus \bar{\mathbb{D}} \rightarrow \widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}$, and the iterates $\{f^n(z)|_{\widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}}\}$ converge locally uniformly to the constant map at ∞ . Similarly, $\{f^n(z)|_{\mathbb{D}}\}$ converge locally uniformly to the constant map at 0.

These sets are maximal for these behaviours, i.e. $\{f^n\}$ is a normal family on \mathbb{D} and on $\widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}$ but on no larger set. If $|z_0| = 1$, then we have for any neighbourhood of z_0 , some points go to infinity and some go to zero, and so there can be no holomorphic limit of iterates on any neighbourhood of z_0 .

4 A More Useful Criterion for Normality

Definition. A family \mathcal{F} of continuous functions $S \rightarrow T$ is *equicontinuous* if, for all $\varepsilon > 0$ there is $\delta > 0$ such that, for all $f \in \mathcal{F}$ and all $s, t \in S$:

$$d_S(s, t) < \delta \implies d_T(f(s), f(t)) < \varepsilon$$

Theorem 4.1 (Arzelà-Ascoli in $\widehat{\mathbb{C}}$). A family $\mathcal{F} : S \rightarrow T$ of continuous maps of domains $S, T \subset \widehat{\mathbb{C}}$ has the property that all sequences have a locally uniformly convergent subsequence if and only if the following are both satisfied:

- \mathcal{F} is equicontinuous on any compact subset of S , and
- For all $z \in S$, $\{f(z) : f \in \mathcal{F}\}$ lies in a compact subset of T .

Proof. The forwards direction is left as an exercise.

For the reverse direction, since $S, T \subseteq \widehat{\mathbb{C}}$, we can fix a countable dense subset $\{z_k\}$ of S . Fix a sequence $\{f_n\}$ of elements of \mathcal{F} . We can find a set of indices $\{n_{ij}\}$ such that:

$$\begin{aligned} n_{11} &< n_{12} < n_{13} < \dots < n_{1j} < \dots \\ n_{21} &< n_{22} < n_{23} < \dots < n_{2j} < \dots \\ &\vdots \\ n_{i1} &< n_{i2} < n_{i3} < \dots < n_{ij} < \dots \end{aligned}$$

so that each row is contained in the previous as a subsequence, and $\lim_{j \rightarrow \infty} f_{n_{kj}}(z_k)$ exists for each k .

The diagonal sequence $g_k := f_{n_{kk}}$ is strictly increasing in index, and for each k , eventually contained in the k^{th} row. So g_k converges at each z_k .

Consider now K , a compact subset of S . Given $\varepsilon > 0$ there is $\delta > 0$ such that, for all $x, y \in K$ and all g_k , $d_S(x, y) < \delta \implies d_T(g_k(x), g_k(y)) < \varepsilon/3$.

Cover K by finitely many $\delta/2$ diameter neighbourhoods, selecting some z_k for each of these neighbourhoods.

Given $z \in K$, we have some z_k with δ , and there are only finitely many z_k in this set, so in fact we can find N such that $n, m > N$ implies $d_T(g_n(z_k), g_m(z_k)) < \frac{\varepsilon}{3}$.

So we have:

$$\begin{aligned} d_T(g_n(z), g_m(z)) &\leq d_T(g_n(z), g_m(z_k)) + d_T(g_n(z_k), g_m(z_k)) + d_T(g_m(z_k), g_m(z)) \\ &< \varepsilon/3 + \varepsilon/3 + \varepsilon/3 \\ &= \varepsilon \end{aligned}$$

Since this holds for all $z \in K$, we have locally uniform convergence as claimed. \square

Corollary 4.1. *If T is compact, a family of continuous maps from S to T is normal if and only if it is equicontinuous on compact subsets.*

This brings us to the critical takeaway applicable to dynamics:

Theorem 4.2 (Montel's theorem). *Let U, V be domains with V hyperbolic. Then the family of holomorphic maps from U to V forms a normal family.*

Proof. Suppose first that U is hyperbolic. By Pick's theorem, the family is equicontinuous.

If $\exists x \in U$ such that $\{f(x) : f \in \mathcal{F}\}$ is in some compact $K \subseteq V$, then again by Pick's theorem, the same is true for all points in U . So by Arzelà-Ascoli, we have a normal family.

Otherwise, we can fix $x \in U, y \in V$, and an infinite sequence $\{f_n\} \subseteq \mathcal{F}$ such that $\rho_V(f_n(x), y) \rightarrow \infty$ as $n \rightarrow \infty$. Fix compact $K \subseteq U, K' \subseteq V$, noting that $\rho_U(x, K), \rho_V(y, K')$ are finite, we have by Pick's theorem that $f_n(K) \cap K' = \emptyset$ for all n sufficiently large. So this sequence diverges locally uniformly, and again we have a normal family.

In the case where U is not hyperbolic, then \mathcal{F} consists of constant maps.

If there is a subsequence with images in a compact set, then we have a locally uniformly convergent subsequence.

If not, then only finitely many of these maps have image in any compact set - we have locally uniform divergence. \square

Example: $f(z) = z^2$. We've seen that $\{f^n(z) : n \in \mathbb{N}\}$ form a normal family on \mathbb{D} and $\widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}$, by manual computation. But since $f^n(\mathbb{D}) \subseteq \mathbb{D}$, $f^n(\widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}) \subseteq \widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}$, the iterates of f must form a normal family on these domains because the image spaces are hyperbolic.

More generally, if $U \subseteq \widehat{\mathbb{C}}$ is a hyperbolic domain, either $\{f^n(U) : n \in \mathbb{N}\}$ covers all but at most 2 points of $\widehat{\mathbb{C}}$, or the iterates of f form a normal family on U .

5 Degree and Ramification

Definition 5.1. A continuous map $f : U \rightarrow V$ of topological spaces is **proper** if for all $K \subset V$, $f^{-1}(K)$ is compact in U .

Lemma 5.1. Let $f : U \rightarrow V$ be continuous. If U is compact and V is Hausdorff, then f is proper.

Proof. Let $K \subseteq V$ be compact. V is Hausdorff $\implies K$ is closed, so $V \setminus K$ is open $\implies f^{-1}(V \setminus K)$ is open (as f is continuous). So $f^{-1}(K) = U \setminus f^{-1}(V \setminus K)$ is closed, and so compact as it is a closed subset of a compact set. So f is proper. \square

Recall from complex analysis the concept of local degree/ramification: if f is holomorphic on a neighbourhood of z_0 , with $f(z_0) = w_0$, then locally we have an expansion

$$f(z) = w_0 + (z - z_0)^e g(z - z_0)$$

where $g(z - z_0)$ is nonzero at z_0 , and holomorphic on a neighbourhood of z_0 . Then e is the local degree/ramification index at z_0 . If $e > 1$, then z_0 is said to be critical.

Let U, V be domains in $\widehat{\mathbb{C}}$.

Proposition 5.1. If $f : U \rightarrow V$ is a proper holomorphic map, then f has a well defined degree on U , equal to

$$\sum_{z \in U: f(z)=w} e_z$$

for any $w \in V$, where e_z is the ramification index of f at z .

Note that this is independent of w , and by Lemma 5.1, all rational maps have well-defined degree!

Theorem 5.1 (Riemann-Hurwitz). Let $f : U \rightarrow V$ be proper of degree d . Then

$$\chi(U) = d\chi(V) - \sum_{p \in V} (e_p - 1)$$

where e_p is the ramification index of f at p and χ is the Euler characteristic.

We will take both of these theorems for granted - they follow immediately from the corresponding statements for compact sets.

Corollary 5.2. Any degree d rational function f has $2d - 2$ critical points, counting multiplicity.

Proof. $\chi(\widehat{\mathbb{C}}) = 2$, and use Riemann-Hurwitz. □

Corollary 5.3. If U, V have $\chi(U) = \chi(V) = 0$, (e.g. annuli, punctured discs), then any proper holomorphic $f : U \rightarrow V$ is unramified.

6 Julia Sets

Definition 6.1 (Fatou Set, Julia Set). Let f be a nonconstant rational map. The **Fatou set** of f is:

$$F(f) := \{x \in \widehat{\mathbb{C}} : \exists \text{ a neighbourhood } U \ni x \text{ on which } \{f^n|_U(z)\} \text{ form a normal family}\}$$

The **Julia set** of f is $J(f) := \widehat{\mathbb{C}} \setminus F(f)$.

Intuitively, $F(f)$ is the stable locus of f , and $J(f)$ is the chaotic or unstable locus of f .

For example, take $f(z) = \lambda z$ for $\lambda = e^{2\pi i \theta}$ for some $\theta \in \mathbb{R} \setminus \mathbb{Q}$. Then $\{f^n(z)\}$ forms a normal family on any disc centered at 0, because $\{f^n|_{\text{disc}}\}$ is a family of self-maps of hyperbolic domains, so we can use Montel's theorem. Note that $f^n(z)$ doesn't converge to any point, but it does have convergent subsequences.

From now on in the course, we will usually only consider rational maps of degree at least 2. In the case of Möbius transformations, the Fatou and Julia sets can be explicitly calculated - see example sheet 1.

6.1 Basic Properties of $J(f)$

It immediately follows from the definition that $F(f)$ is open, and so $J(f)$ is closed and compact in $\widehat{\mathbb{C}}$.

Lemma 6.2. The Fatou and Julia sets of f are totally invariant under f . That is, $f(J(f)) = J(f) = f^{-1}(J(f))$, and similarly for $F(f)$.

Proof. It suffices to show that $f^{-1}(F(f)) = F(f)$, and so to prove that, for any open $U \subseteq \widehat{\mathbb{C}}$, a sequence of iterates $f^{n_k}(z)$ converges uniformly on compact subsets of U if and only if $f^{n_k+1}(z)$ converges uniformly on compact subsets of $f^{-1}(U)$.

We have:

$$\sup_{z \in K} d(f^{n_j+1}(z), f^{n_k+1}(z)) = \sup_{w \in f(K)} d(f^{n_j}(w), f^{n_k}(w))$$

Since f is proper and continuous, preimages and images of compact sets are compact, and so we have the desired equivalence. \square

This tells us why we get self similarity in Julia sets: if $z \in J(f)$ and $f'(z) \neq 0$, then there is a neighbourhood N of z such that $f : N \rightarrow f(N)$ is a conformal equivalence. Since $N \cap J(f) \xrightarrow{f} f(N) \cap J(f)$, we have self-similarity.

Lemma 6.3. $J(f) = J(f^n)$ for any iterate f^n of f , and similarly for the Fatou set.

Lemma 6.4. Let f be a rational map and μ a Möbius transformation, we define $g := \mu \circ f \circ \mu^{-1}$. Then $\mu(J(f)) = J(g)$.

The proofs of these are exercises on example sheet 1.

6.2 Conjugation and Dynamics

In general, if μ is a Möbius map, and f is rational, with $g := \mu \circ f \circ \mu^{-1}$, then $g^n = \mu \circ f^n \circ \mu^{-1}$.

As an example, let f be a rational map of degree 2 with two fixed critical points. If ∞ is fixed, and ∞ maps to itself with degree 2, then we know ∞ has no other preimages, and we have a polynomial of degree 2. Let's conjugate by μ , a Möbius map taking one of the fixed critical points to 0 , and the other to 0 .²

So we are conjugate to a degree 2 polynomial with 0 fixed and critical, i.e. $f(z) = az^2$. Conjugating again by $\mu(z) = az$, which doesn't change 0 or ∞ , we have a map conjugate to $g(z) = z^2$. This has the unit circle as its Julia set.

Therefore f 's Julia set is a Möbius image of the unit circle, i.e. a circle.

Theorem 6.5. Let $z \in J(f)$ and U be an open neighbourhood of z . Then the union $V := \bigcup f^n(U)$ of forward images of U contains all but at most two points of the Riemann sphere, both of which are critical points in the Fatou set.

Proof. If $\{f^n|_U\}$ omit at least 3 points of $\widehat{\mathbb{C}}$, then Montel's theorem tells us we have a normal family on U , and so $U \subseteq F(f)$. But $U \cap J(f) \neq \emptyset$.

If $\bigcup f^n(U)$ misses any points, then we want to show they are Fatou and critical. Without loss of generality, assume these points are in $\{0, \infty\}$. Since $f(V) \subseteq V$, no preimage of 0 or ∞ lies in V .

So the only possible behaviours are:

1. $0 \mapsto 0, \infty \mapsto \infty$, both with degree $d = \deg f \geq 2$
2. $0 \mapsto \infty, \infty \mapsto 0$, both with degree d
3. $\infty \mapsto \infty$ with degree d

²Notice that being fixed and critical are conjugation invariant

4. No points in this set.

Hence all points in the set are critical, as they are images of ramification degree $d > 1$.

In case 1, $f(z) = az^d$, conjugate to z^d , with $0, \infty$ Fatou.

In case 2, $f(z) = \frac{a}{z^d}$, conjugate to z^{-d} , with Julia set a circle again, so $0, \infty$ Fatou.

In case 3, $f(z)$ is a polynomial map, and so ∞ is Fatou. \square

Corollary 6.6. *If the Julia set contains an interior point, then $J(f) = \widehat{\mathbb{C}}$.*

Proof. By the previous theorem and forward invariance of the Julia set, if U is open and contained in $J(f)$, then $\bigcup f^n(U) \subseteq J(f)$ contains all but at most two points of $\widehat{\mathbb{C}}$. But $J(f)$ is closed, hence $J(f) = \widehat{\mathbb{C}}$. \square

The Julia set is the smallest closed totally invariant set in $\widehat{\mathbb{C}}$ containing at least 3 points.

Note that $J(f) = \widehat{\mathbb{C}}$ can happen, but not with polynomial maps. For instance, take $f(z) = \frac{1}{1-2z^2}$ - by the end of the course we'll be able to prove this function is chaotic everywhere.

On the other hand, we will show soon that $J(f) \neq \emptyset$.

7 Cycles and Multipliers

Definition 7.1. *Let $z_0 \in \widehat{\mathbb{C}}$. We say that z_0 is **periodic** or in a **periodic cycle** for f if $f^m(z_0) = z_0$ for some $m \in \mathbb{N}$. The minimal such m is the period of the cycle. If z_0 has period m , then the derivative*

$$\lambda := (f^m)'(z_0) = \prod_{i=0}^{m-1} f'(f^i(z_0))$$

*is called the **multiplier** of the cycle.*

Example: Take $p(z) = a_d z^d + \dots + a_0$ a polynomial, so that $p(\infty) = \infty$. Then ∞ is in a cycle of period 1. By example sheet 1, $p'(\infty) = \lim_{z \rightarrow \infty} \frac{1}{p'(z)} = 0$. Hence ∞ is a fixed point of multiplier zero for any polynomial.

We classify periodic cycles according to their multiplier:

Definition 7.2. *Let z_0 be a point of period m for f with multiplier λ . Then we say z_0 is:*

- **superattracting** if $\lambda = 0$
- **attracting** if $|\lambda| < 1$
- **indifferent** if $|\lambda| = 1$
- **repelling** if $|\lambda| > 1$

Note that superattracting \implies attracting.

If $g = \mu \circ f \circ \mu^{-1}$ for μ a Möbius map, and z_0 has period m for f with multiplier λ , then $\mu(z_0)$ has period m for g , again with multiplier λ .

Definition 7.3. Suppose $C := \{z_0, \dots, z_{m-1}\}$ is an attracting orbit of period m . Then the **basin of attraction** for the cycle C is the set:

$$\mathcal{A} := \{z \in \widehat{\mathbb{C}} : \lim_{n \rightarrow \infty} f^{nm}(z) \in C\}$$

For example, take $f(z) = z^2, f'(z) = 2z$. Then if z is a periodic point with period m , then $z = z^{2^m}$. These points are:

- 0
- ∞
- Roots of unity of the form $z^{2^m-1} = 1$

These points respectively have multipliers:

- $\lambda = 2 \cdot 0 = 0$, and the basin of attraction is $|z| < 1$.
- $\lambda = \lim_{z \rightarrow \infty} \frac{1}{2z} = 0$, and the basin of attraction is $|z| > 1$.
- $|\lambda| = 2|z| = 2$, so these are repelling.

Theorem 7.4. Every attracting basin is contained in the Fatou set. Any repelling periodic point is contained in the Julia set.

Proof. Since $J(f) = J(f^m)$ for $m \in \mathbb{N}$, we may assume that z_0 is a fixed point of f with multiplier λ . Suppose that $|\lambda| < 1$. Then locally, by Taylor's theorem, we have $|f(z) - z_0| \leq c|z - z_0|$ for any constant $|\lambda| < c < 1$. So we have uniform convergence of the iterates on compact subsets on a neighbourhood of z_0 to the constant function $z \mapsto z_0$. So $z_0 \in F(f)$ as claimed.

If $z \in J(f)$, with $\lim_{n \rightarrow \infty} f^n(z) = z_1$ say, then $z_1 \in J(f)$. But by above, $z_1 \in F(f)$. Hence the attracting basin of an attracting point is also Fatou.

Suppose $|\lambda| > 1$. The derivative at z_0 of the iterates $f^k(z)$ is $\lambda^k \rightarrow \infty$ as $k \rightarrow \infty$. So there is no equicontinuity of $\{f^k\}$ on any neighbourhood of z_0 , and so by Arzelà-Ascoli, $\{f^k\}$ is not normal on a neighbourhood of z_0 . Hence $z_0 \in J(f)$. \square

The derivative at fixed points is a local property, but it turns out there is still some global constraints on the multipliers of fixed points.

Definition 7.5. Let z_0 be a fixed point of a rational map f of degree d . The **residue index** of f at z_0 is

$$i_f(z_0) := \frac{1}{2\pi i} \int_{\gamma} \frac{dz}{z - f(z)}$$

where γ is any small positively oriented loop around z_0 .

Note: a degree d map has $d + 1$ fixed points.

Lemma 7.6. Let λ be the multiplier of a fixed point z_0 of f . If $\lambda \neq 1$, then

$$i_f(z_0) = \frac{1}{1 - \lambda}$$

Proof. Without loss of generality, assume that $z_0 = 0$ or $z_0 = \infty$, after noticing that both the residue and the multiplier are invariant under conjugation by a translation.

If $z_0 = 0$, then $f(z) = \lambda z + a_2 z^2 + a_3 z^3 + \dots$ near $z_0 = 0$. Since $\lambda \neq 1$, we have

$$\begin{aligned} z - f(z) &= (1 - \lambda)z(1 + b_1 z + b_2 z^2 + \dots) \\ \implies \frac{1}{z - f(z)} &= \frac{1}{(1 - \lambda)z} \frac{1}{1 + b_1 z + b_2 z^2 + \dots} \\ &= \frac{1}{(1 - \lambda)z} (1 + c_1 z + c_2 z^2 + \dots) \\ &= \frac{1}{(1 - \lambda)z} + g(z) \end{aligned}$$

where $g(z)$ is holomorphic. Integrating both sides causes the $g(z)$ to disappear, and so by the residue theorem we have the result.

If $z_0 = \infty$, a similar computation works. □

On example sheet 1, there is an exercise to show that the residue index is conjugation invariant by any Möbius map. Note that this lemma deals with every case except for when $\lambda = 1$.

Theorem 7.7 (Holomorphic Lefschetz on the Riemann Sphere). *Let $f : \widehat{\mathbb{C}} \rightarrow \widehat{\mathbb{C}}$ be a rational map of degree at least 2. Then*

$$\sum_{z=f(z)} i_f(z) = 1$$

Proof. Assume without loss of generality that ∞ is not a fixed point. Let C_R denote the circle of radius R about 0, positively oriented, and suppose that it is large enough to strictly contain all the fixed points of f . Then with $w = \frac{1}{z}$:

$$\int_{C_R} \frac{dz}{z - f(z)} = \int_{-C_{1/R}} \frac{-dw}{w^2 \left(\frac{1}{w} - f\left(\frac{1}{w}\right) \right)} = \int_{C_{1/R}} \frac{dw}{w \left(1 - w f\left(\frac{1}{w}\right) \right)}$$

The nonzero poles of the integral are reciprocals of the fixed points of f , which by construction lie outside $C_{1/R}$. So, by the residue theorem, :

$$\sum_{z=f(z)} i_f(z) = \frac{1}{2\pi i} \int_{C_R} \frac{dz}{z - f(z)} = \operatorname{Res}_{w=0} \left[\frac{1}{w \left(1 - w f\left(\frac{1}{w}\right) \right)} \right] = 1$$

□

7.1 Structure of the Julia Set

We have shown already that $J(f)$ is compact, and has no interior points unless $J(f) = \widehat{\mathbb{C}}$. In this section we will show some other structural properties, starting with the following corollary of 7.7

Corollary 7.8. *A rational map f of degree $d \geq 2$ has a nonempty Julia set.*

Proof. Suppose that $J(f) = \emptyset$, and f is of degree $d \geq 2$, so that f has $d + 1$ fixed points, counting with multiplicity.

Since any repelling fixed point lies in $J(f)$, we can assume that $|\lambda| \leq 1$ for all fixed points of f . Suppose first that no fixed point has multiplier 1. Then the derivative of $f(z) - z$ is $f'(z) - 1$, so we have all of the $d + 1$ fixed points of f distinct, as $f'(z) \neq 1$. Then all multipliers lie in \mathbb{D} , and the map $x \mapsto \frac{1}{1-x}$, so that $\lambda(z) \mapsto i_f(z)$, is a Möbius transformation taking \mathbb{D} to $\{z : \Re(z) \geq \frac{1}{2}\}$. So the sum of the $i_f(z)$ has real part $\geq \frac{d+1}{2} > 1$, violating 7.7.

Suppose now that $\lambda = 1$ for some fixed point $f(z_0) = z_0$ - wlog, move it to 0. Then locally, $f(z) = z + a_k z^k + \dots$, $a_k \neq 0$, and so:

$$f^n(z) = z + n a_k z^k + \dots$$

Hence the k^{th} derivative of f^n at z_0 tends to ∞ as $n \rightarrow \infty$, and so we don't have normality on any neighbourhood of z_0 , and so $z_0 \in J(f)$. \square

In fact, we have proved something slightly stronger. We've proved that:

1. Any periodic cycle with $\lambda^k = 1$ for some $k \in \mathbb{N}$ is contained in $J(f)$.

If λ is a multiplier with $\lambda^k = 1$ for some $k \in \mathbb{N}$, f^k has a periodic cycle with $\lambda = 1$, and so the cycle is contained in $J(f^k)$. Since $J(f) = J(f^k)$, any such cycle is contained in $J(f)$.

2. $J(f)$ is infinite.

We produced a fixed point z_0 with $|\lambda| \geq 1$ and $z_0 \in J(f)$. Consider $S = \bigcup_{n \in \mathbb{N} \cup \{0\}} f^{-n}(z_0) \subseteq J(f)$. If this is finite, then since all elements' preimages are still in the set, f must act as a bijection on S . Since $f(z_0) = z_0$, z_0 is its only preimage, so $f'(z_0) = 0$, \nmid .

Example: $f(z) = z^2 + \frac{1}{4}$. Consider the fixed points: $f(\infty) = \infty$, $f(1/2) = 1/2$. ∞ has multiplier 0, and is mapped to itself with degree 2. $\frac{1}{2}$ has multiplier 1, so lies in $J(f)$, as do its infinitely many iterated preimages.

Proposition 7.9. *If $\mathcal{A} \subset \widehat{\mathbb{C}}$ is the attracting basin of a periodic orbit for f . Then the Julia set $J(f)$ is the topological boundary $\partial \mathcal{A}$ of \mathcal{A} .*

Proof. Let U be an open neighbourhood intersecting $J(f)$. Then we have already seen that $\bigcup_{n \in \mathbb{N}} f^n(U)$ contains all but at most 2 points of $\widehat{\mathbb{C}}$, and so intersects \mathcal{A} , i.e., $f^n(U) \cap \mathcal{A} = \emptyset$ for some $n \in \mathbb{N}$.

U was arbitrary, and hence $J(f) \subseteq \bar{\mathcal{A}}$. Then $J(f) \cap \mathcal{A} = \emptyset \implies J(f) \subseteq \partial \mathcal{A}$.

Now suppose that $z \in \partial \mathcal{A}$. If U is a neighbourhood of z on which the iterates form a normal family (i.e. $z \in F(f)$), then pick a convergent subsequence of $\{f^k\}$ converging to g , holomorphic on U . Then $g|_U$ on $U \cap \mathcal{A}$ takes one of a finite number of values, namely the elements of the cycle with \mathcal{A} is attracting to. So g must be constant as it is holomorphic. Hence $U \subseteq \mathcal{A}$, contradicting that $z \in \partial \mathcal{A}$. Therefore $z \notin F(f)$, i.e. $z \in J(f)$. Hence $\partial \mathcal{A} \subseteq J(f)$. \square

Example: Consider again $f(z) = z^2$. Then, given $\alpha = \exp(2\pi i \theta) \in J(f)$, the preimages of α are all the numbers which are a root of $z^{2^m} - \alpha = 0$ for some $m \in \mathbb{N}$, i.e. $\{\exp(2\pi i \frac{\theta+k}{2^m}) : m \in \mathbb{N}, 0 \leq k < 2^m\}$. These points provide a dense subset of $J(f)$, the unit circle.

Corollary 7.10. For any rational map f and $z_0 \in J(f)$, the set of preimages

$$\{z : f^n(z) = z_0 \text{ for some } n \geq 0\}$$

form a dense subset of $J(f)$.

Proof. If we fix $z_0, z_1 \in J(f)$, if z_1 is not approximated by preimages of z_0 , then there is some neighbourhood U of z_1 whose forward images don't contain z_0 . But these forward images contain all but at most 2 Fatou points of $\widehat{\mathbb{C}}$, and in particular contain the Julia set, and hence $z_0 \notin U$. \square

Definition 7.11. A set is **perfect** if it is closed with no isolated points, or equivalently is equal to its set of limit points.

$J(f)$ is thus a perfect set: it is closed and infinite, so it contains at least one non-isolated point z_0 . The preimages of z_0 form a dense non-isolated subset of the Julia set, so no point of $J(f)$ is isolated.

8 Local Dynamics of Attractors

Shröder's equation: when is there a conformal change of variable ϕ so that $\phi(f(z)) = \lambda(\phi(z))$ on a neighbourhood of a fixed point p for f , where λ is the multiplier of that fixed point?

Theorem 8.1 (Koenig's Linearization Theorem). Let p be a fixed point of f with multiplier λ satisfying $|\lambda| \neq 0, 1$. Then there exists a local holomorphic change of coordinates $w = \phi(z)$ so that $\phi(p) = 0$ and $\phi \circ f \circ \phi^{-1}(w) = \lambda w$ for all w in some neighbourhood U of p , so that the diagram

$$\begin{array}{ccc} U & \xrightarrow{f} & f(U) \\ \downarrow \phi & & \downarrow \phi \\ \mathbb{C} & \xrightarrow{\lambda} & \mathbb{C} \end{array}$$

commutes. This change of coordinates is unique up to multiplication by a constant.

Proof. The idea is to prove that $\lim_{n \rightarrow \infty} \frac{f^n(z)}{\lambda^n}$ exists as a holomorphic function on a neighbourhood of p , and then we're almost done.

Conjugate to assume that $p = 0$. Now suppose $|\lambda| < 1$. Then there is a constant c such that $c^2 < |\lambda| < c < 1$. By Taylor's theorem, there is $r > 0$ such that, on $D(0, r)$, we have $|f(z)| \leq c|z|$. So for $z \in D(0, r)$ we have geometric convergence $|f^n(z)| \leq rc^n$. Again by Taylor, we have some constant B such that $|f(z) - \lambda z| \leq B|z|^2$ on $D(0, r)$ (shrinking r if necessarily). Hence for $z \in D(0, r)$:

$$\begin{aligned} |f^{n+1}(z) - \lambda f^n(z)| &\leq B|f^n(z)|^2 \leq Br^2 c^{2n} \\ \implies \left| \frac{f^{n+1}(z)}{\lambda^{n+1}} - \frac{f^n(z)}{\lambda^n} \right| &\leq B \left(\frac{r^2}{|\lambda|} \right) \left(\frac{c^2}{|\lambda|} \right)^n \rightarrow 0 \text{ as } n \rightarrow \infty \end{aligned}$$

So $\frac{f^n(z)}{\lambda^n}$ converge uniformly on compact subsets of $D(0, r)$, to a holomorphic limit

$$\phi(z) := \lim_{n \rightarrow \infty} \frac{f^n(z)}{\lambda^n}$$

We have $\phi(f(z)) = \lambda\phi(z)$, and $\phi'(0) = 1$ as $z \mapsto \frac{f^n(z)}{\lambda^n}$ has derivative 1 at 0 for all n .

So ϕ is conformal on a neighbourhood of 0.

To show that this is unique, suppose ψ is another such. Then we have a commutative diagram:

$$\begin{array}{ccc} V & \xrightarrow{\lambda} & \lambda \cdot V \\ \downarrow \psi^{-1} & & \downarrow \psi^{-1} \\ U & \xrightarrow{f} & f(U) \\ \downarrow \phi & & \downarrow \phi \\ \mathbb{C} & \xrightarrow{\lambda} & \mathbb{C} \end{array} \quad \begin{array}{ccc} w & \mapsto & \lambda w \\ \downarrow & & \downarrow \\ \psi^{-1}(w) & \mapsto & \psi^{-1}(\lambda w) = f(\psi^{-1}(w)) \\ \downarrow & & \downarrow \\ \phi(\psi^{-1}(w)) & \mapsto & \lambda\phi(\psi^{-1}(w)) = \phi(\psi^{-1}(\lambda w)) \end{array}$$

Hence $\lambda\phi(\psi^{-1}(w)) = \phi(\psi^{-1}(\lambda w))$. So $\phi \circ \psi^{-1}$ is conformal, on a neighbourhood of 0, fixes 0, and commutes with λ . Taking a Taylor series,

$$\begin{aligned} \phi \circ \psi^{-1} : w &\mapsto a_1 w + a_2 w^2 + \dots \\ \lambda w &\mapsto a_1(\lambda w) + a_2(\lambda^2 w^2) + \dots = \lambda(a_1 w + a_2 w^2 + \dots) \end{aligned}$$

By uniqueness of Taylor series, $\lambda a_k = \lambda^k a_k$ for all $k \in \mathbb{N}$, and so, since $|\lambda| \neq 0, 1$, $a_k = 0$ for $k \geq 2$. So $\phi \circ \psi^{-1}(w) = a_1 w$. Apply for f^{-1} for the repelling case. \square

Corollary 8.2. Suppose p is an attracting fixed point of f with multiplier $\lambda \neq 0$ and basin of attraction \mathcal{A} . Then there is a holomorphic (not necessarily conformal) map $\phi : \mathcal{A} \rightarrow \mathbb{C}$ so that the following diagram commutes:

$$\begin{array}{ccc} \mathcal{A} & \xrightarrow{f} & \mathcal{A} \\ \downarrow \phi & & \downarrow \phi \\ \mathbb{C} & \xrightarrow{\lambda} & \mathbb{C} \end{array}$$

which is biholomorphic on a neighbourhood of p and unique up to multiplication by a constant.

Proof. Define by the previous theorem ϕ on a neighbourhood of p , $\phi(p) = 0$, $\phi(f(z)) = \lambda\phi(z)$. Then for all $z \in \mathcal{A}$, there is by definition some $n \in \mathbb{N}$ such that $f^n(z) \in \text{dom } \phi$. Thus:

$$\phi(z) := \lim_{n \rightarrow \infty} \frac{\phi(f^n(z))}{\lambda^n}$$

satisfies the corollary. \square

Definition 8.3. A fixed point p of f is **topologically attracting** if there is a neighbourhood U of p such that $\{f^n\}$ converges locally uniformly to the constant map $z \mapsto p$ on U .

If p is topologically attracting, then $p \notin J(f)$.

Lemma 8.4. A fixed point p is topologically attracting if and only if it is attracting, that is, if and only if $|f'(p)| = |\lambda| < 1$.

Proof. We've shown that attracting implies topologically attracting via Taylor's theorem. If p is topologically attracting, then there is a disc $D(p, r)$ for $r > 0$ and some iterate f^n such that $f^n(D(0, r)) \subseteq D(0, r)$.

Then Schwarz's lemma implies that $|(f^n)'(p)| = |\lambda|^n < 1$, so $|\lambda| < 1$. \square

8.1 Generalizing to Period > 1

If $\{z_0, \dots, z_{n-1}\}$ is an attracting cycle, so that z_i is an attracting fixed point of f^n , each with attracting basing \mathcal{A}_i (under f^n).

The \mathcal{A}_i are permuted by f , so that $f(\mathcal{A}_i) = \mathcal{A}_{i+1}$ - this is an exercise on ES1.

Then we generalise to the commutative diagram

$$\begin{array}{ccccccc} \mathcal{A}_0 & \xrightarrow{f} & \mathcal{A}_1 & \xrightarrow{f} & \dots & \xrightarrow{f} & \mathcal{A}_{n-1} & \xrightarrow{f} & \mathcal{A}_0 \\ \downarrow \phi_0 & & \downarrow \phi_1 & & & & \downarrow \phi_{n-1} & & \downarrow \phi_0 \\ \mathbb{C} & \xrightarrow{\lambda_0} & \mathbb{C} & \xrightarrow{\lambda_1} & \dots & \xrightarrow{\lambda_{n-2}} & \mathbb{C} & \xrightarrow{\lambda_{n-1}} & \mathbb{C} \end{array}$$

where $\lambda_k = f'(z_k)$.

Definition 8.5. The **immediate basin** of an attracting cycle is the union of connected components of the Fatou set containing all cycle elements.

Note that this is not iteration invariant. E.g. if we have a 3-cycle between Fatou components, then the immediate basin of a cycle $z_0 \rightarrow z_1 \rightarrow z_2 \rightarrow z_0$ under f will not be the same as the immediate basin of z_0 under f^3 .

Theorem 8.6. Suppose $f : \widehat{\mathbb{C}} \rightarrow \widehat{\mathbb{C}}$ has degree $d \geq 2$. Then every attracting fixed point of f has a critical point in its immediate basin. Consequently, f has at most $2d - 2$ attracting cycles.

Proof. A fixed attractor has connected immediate basin, so call it U . U is hyperbolic since $J(f)$ is infinite, so we have

$$\begin{array}{ccc} \mathbb{D} & \xrightarrow{F} & \mathbb{D} \\ \downarrow \pi & & \downarrow \pi \\ U & \xrightarrow{f} & U \end{array}$$

If U has no critical point, $f \circ \pi$ doesn't either, so is a covering map itself. So by universality there is $G : \mathbb{D} \rightarrow \mathbb{D}$ so that

$$\begin{array}{ccc} \mathbb{D} & \xleftarrow{G} & \mathbb{D} \\ \downarrow \pi & & \downarrow \pi \\ U & \xrightarrow{f} & U \end{array}$$

commutes, as \mathbb{D} is the universal cover of U . Choosing the fixed point of U to lift to 0, choose lifts F, G to each fix 0. Then G is an inverse to F , so F is a disc automorphism, contradicting 0 being attracting. \square

If $z_0 \mapsto z_1 \mapsto \dots \mapsto z_{n-1} \mapsto z_0$ is an attracting cycle of period n for f , then let A_i be the immediate basin of f^n for z_i . If $\bigcup_i A_i$ contains no critical point of f , since $f(A_i) = A_{i+1 \bmod n}$ and $(f^n)'(z) = \prod_{i=0}^{n-1} f'(f^i(z_0))$, we see that there can be no critical points of f^n in A_i for any i , contradicting what we just proved.

So the immediate basin of every attracting cycle contains a critical point of f . f has at most $2d - 2$ critical points, and so we can only have $2d - 2$ attracting cycles.

Theorem 8.7. *Suppose $f(0) = 0$ is attracting for f , with multiplier $\lambda \neq 0$, immediate basin \mathcal{A}_0 , and linearizing coordinate ϕ with local inverse $\psi : \mathbb{D}(0, \varepsilon) \rightarrow \mathcal{A}_0$. Then ψ extends by analytic continuation to a maximal open disc $\mathbb{D}(0, r)$, extends homeomorphically over the boundary circle $\partial\mathbb{D}(0, r)$, and the image $\psi(\partial\mathbb{D}(0, r)) \subset \mathcal{A}_0$ contains a critical point.*

Example: Take $f_c(z) = z^2 + c$ for $c \in \mathbb{C}$.

We know that f_c has a critical point at ∞ of multiplicity 2. Since $2 \cdot 2 - 2 = 2$, we have exactly one other critical point, which is at 0. By 8.6, there is at most one attracting cycle other than ∞ .

Suppose we have fixed point attractor: then z_0 fixed implies that $c = z_0 - z_0^2$, and z_0 attracting, since $\lambda = f'(z_0) = 2z_0$, happens if and only if $|z_0| < \frac{1}{2}$. So the set of parameters c with an attracting fixed point is the image of $\mathbb{D}(0, \frac{1}{2})$ under $z_0 \mapsto z_0 - z_0^2$, i.e. the image of \mathbb{D} under $\lambda \mapsto \frac{\lambda}{2} - \left(\frac{\lambda}{2}\right)^2$, a cardioid.

Suppose we have a period 2 attractor: then $(z_0^2 + c)^2 + c = z_0$, and z_0 not fixed.

$$z_0^4 + 2cz_0^2 - z_0 + c^2 + c = 0 \iff (z_0^2 - z_0 + c)(z_0^2 + z_0 + c + 1) = 0$$

The roots of the first factor are fixed, so we want the roots of $z_0^2 + z_0 + c + 1$. So $c + 1 = -z_0^2 - z_0$. The multiplier for a period 2 point z_0 is $\lambda = 4z_0(z_0^2 + c) = 4z_0(z_0^2 - z_0^2 - z_0 - 1) = 4z_0(-z_0 - 1) = 4(c + 1)$. Hence the parameters with a period 2 attractor is the image of \mathbb{D} under $\lambda \mapsto \frac{\lambda}{4} - 1$, i.e. $\mathbb{D}(-1, \frac{1}{4})$.

Figure 7: Figure showing the locus of c leading to attracting period n points in f_c . Source: wikimedia commons

As a point of caution, note that attracting basins need not be connected. In fact, disconnected Julia sets have many components.

Theorem 8.8. *If a rational map f has disconnected Julia set, then $J(f)$ has uncountably many connected components.*

Proof. Suppose $J(f)$ is not connected, so that $J(f) = J_0 \cup J_1$, two non-empty disjoint compact infinite subsets of $J(f)$. Given $z \in J(f)$, we assign a sequence of values $\{\beta_n(z)\}$ of 0s and 1s, with $\beta_n(z) = 0$ if $f^n(z) \in J_0$, and 1 otherwise. 2 points in the same connected components have the same sequence since f is continuous. So $\beta : z \rightarrow \{(\beta_n)\}$ is a map from the connected components of $J(f)$ to $\{0, 1\}^{\mathbb{N}}$.

Let $(\beta_0(z), \dots, \beta_k(z))$ be some finite piece of the sequence for fixed $z \in J(f)$. If we can show that there is $z' \in J(f)$ such that $\beta_i(z') = \beta_i(z)$ for all $0 \leq i \leq k$, but there is $n > k$ such that $\beta_n(z') \neq \beta_n(z)$, then β will have an uncountable image, and we will be done.

Define $U_{z,k} := \{w \in \widehat{\mathbb{C}} : f^i(w) \notin J_{1-\beta_i(z)} \forall 0 \leq i \leq k\}$. Note that $U_{z,k}$ is open and contains the Fatou set for all z, k .

Choose a constant subsequence $(\beta_{n_j}(z))$, say always taking the value $\beta_0(z)$. If $z' \in J(f)$ with $\beta_i(z') = \beta_i(z)$ for all $0 \leq i \leq k$, then $z' \in U_{z,k}$, and if $z' \in F(f)$, $z' \in U_{z,k}$. If, for any z' with $\beta_i(z) = \beta_i(z')$ for all $0 \leq i \leq k$, then $\beta_n(z) = \beta_n(z')$ for all n , then $\beta_{n_j}(z) = \beta_{n_j}(z')$ for all j .

I.e. $f^{n_j}(z') \in U_{z,n_j} = U_{z,0}$. So $f^{n_j}|_{U_{z,k}} : U_{z,k} \rightarrow U_{z,0}$. Since J_0, J_1 are infinite, $U_{z,0}$ is hyperbolic, and so by Montel's theorem, we have a normal family, and $U_{z,k} \subseteq F(f)$.

Hence the image of β is uncountable. \square

Theorem 8.9 (Böttcher 1904). *Suppose $f(0) = 0$ is holomorphic, with local expansion*

$$f(z) = a_m z^m + a_{m+1} z^{m+1} + \dots, m \geq 2$$

Then there is a holomorphic local change of coordinate ϕ with $\phi(0) = 0$ so that $\phi(f(z)) = \phi(z)^m$. ϕ is unique up to multiplication by an $(m-1)^{\text{st}}$ root of unity.

Proof. This proof is similar to the proof of Koenig's theorem.

Assume by conjugating with an $(m-1)^{\text{st}}$ root a_m , say α , that $a_m = 1$. So we write

$$f(z) = z^m(1 + h(z))$$

where h is holomorphic on a neighbourhood of 0, and $h(0) = 0$.

We have a holomorphic logarithm $k(z)$ of $1+h(z)$ on a small neighbourhood of 0, so $1+h(z) = e^{k(z)}$. By induction, we see that

$$f^n(z) = z^{m^n} e^{k_n(z)}, \quad k_n(z) \text{ holomorphic}$$

We have a branch of $(f^n)^{1/m^n}$ on this neighbourhood of 0, so choose the one with

$$\phi_n(z) := f^n(z)^{1/m^n} = z(1 + O(z))$$

Then it can be checked that $\lim_{n \rightarrow \infty} \phi_n(z)$ converges uniformly on compact subsets of the neighbourhood, and satisfies the functional equation $\phi(f(z)) = \phi(z)^m$, $\phi(0) = 0$, and ϕ is conformal.

Uniqueness follows from the uniqueness of Taylor expansions, as in the case of the Koenig linearization. \square

Note that there is no real hope of a global extension to the entire immediate basin like we do with non-superattracting points. What we can do though is:

Corollary 8.10. *Let $f(0) = 0$ be a superattracting fixed point for f with basin of attraction \mathcal{A} , and let ϕ be a Böttcher coordinate on a neighbourhood of 0. Then $z \mapsto |\phi(z)|$ extends uniquely to a continuous map $|\phi| : \mathcal{A} \rightarrow [0, 1)$ satisfying $|\phi(f(z))| = |\phi(z)|^m$ for all $z \in \mathcal{A}$.*

Proof. Given $z \in \mathcal{A}$, find $n \gg 1$, so that $f^n(z)$ lies in the domain of the Böttcher coordinate. Set

$$|\phi(z)| := |\phi(f^n(z))|^{1/m^n}$$

The rest follows: $|\phi|$ is continuous, satisfies the identity required, and is unique. \square

Remark: Böttcher for polynomials. Polynomials have superattracting fixed points at ∞ . We will often call $\frac{1}{\phi(z)}$ the/a Böttcher coordinate at ∞ , where

Example: Consider Newton's method: $f(z) = z - \frac{p(z)}{p'(z)}$. The roots of $p(z)$ are the fixed points of f .

$f'(z) = \frac{p(z)p''(z)}{p'(z)^2}$, so the roots of p are also critical for f , and hence are superattracting fixed points.

If $\deg(p) = d = \deg(f)$, then we have $d + 1$ fixed points. d of them are these superattracting fixed points, so by the holomorphic fixed point formula, the other one, ∞ , has multiplier $\frac{d}{d-1}$, so is repelling.

For example, the family $p_c(z) = (z - 1)(z - c + 0.5)(z + c + 0.5)$, has Newton maps $f_c(z) = z - \frac{(z-1)(z-c+0.5)(z+c+0.5)}{3z^3 - c^2 - 0.75}$. There is one "free" critical point at 0, which suggests a colouring of \mathbb{C} : colour c green, red, or blue, depending on if 0 is attracted to 1, $-c - \frac{1}{2}$, $c - \frac{1}{2}$ respectively, which I'll add to these notes once I find a picture of it.

8.2 Polynomial Maps

Definition 8.11. Let $f(z) = a_d z^d + a_{d-1} z^{d-1} + \dots + a_0$ be a polynomial of degree $d \geq 2$. The **filled Julia set** of f is

$$K(f) := \{z \in \mathbb{C} : f^n(z) \not\rightarrow \infty \text{ as } n \rightarrow \infty\}$$

Corollary 8.12. Let $f(z)$ be a polynomial of degree $d \geq 2$. Then $\partial K(f) = J(f)$.

Proof. f is a polynomial, so ∞ is a superattracting fixed point. Hence if $B(\infty)$ is the attracting basin for ∞ , then $K(f) = \widehat{\mathbb{C}} \setminus B(\infty)$. So $\partial K(f) = \partial B(\infty) = J(f)$. \square

We also have another notion of the rate of divergence to ∞ :

Definition 8.13. Let $f(z)$ be a polynomial of degree $d \geq 2$. Then the **Green's function** associated to f is

$$G_f(z) := \lim_{n \rightarrow \infty} \frac{\log^+ |f^n(z)|}{d^n}$$

where $\log^+ x = \max\{0, \log x\}$ for any $x \geq 0$.

In fact, this carries the same information as $|\phi|$:

Lemma 8.14. G_f for a polynomial f satisfies:

1. G_f is continuous everywhere and harmonic on $\widehat{\mathbb{C}} \setminus K(f)$.
2. $G_f(z) = \log |z| + O(1)$ as $|z| \rightarrow \infty$.
3. $G_f(z) \rightarrow 0$ as $z \rightarrow K(f)$.
4. $G_f(f(z)) = d G_f(z)$

And moreover, $G_f(z)$ is uniquely characterised by properties 1, 2, and 4. Additionally, for $z \notin K(f)$:

$$G_f(z) = \log |\phi_f(z)|$$

where $|\phi_f|$ is the extended Böttcher coordinate on the basin of infinity.

Proof. Consider the function $\log^+ |f(z)| - d \log^+ |z| : \widehat{\mathbb{C}} \rightarrow \mathbb{R} \cup \{\infty\}$ is continuous, and in fact bounded, by some constant C , since f is a polynomial of degree d . So

$$\left| \frac{\log^+ |f^n(z)|}{d^n} - \frac{\log^+ |f^{n-1}(z)|}{d^{n-1}} \right| \leq \frac{C}{d^n}$$

Hence, if $m < n$:

$$\begin{aligned} \left| \frac{\log^+ |f^n(z)|}{d^n} - \frac{\log^+ |f^m(z)|}{d^m} \right| &\leq \sum_{k=m}^{n-1} \left| \frac{\log^+ |f^{k+1}(z)|}{d^{k+1}} - \frac{\log^+ |f^k(z)|}{d^k} \right| \\ &\leq \sum_{k=m}^{n-1} \frac{C}{d^{k+1}} \\ &\leq \frac{C}{d^m(d-1)} \end{aligned}$$

So the limit in the definition of G_f was uniform, and hence G_f is a uniform limit of continuous functions, hence continuous.

For property 2, take $m = 0$, so $\left| \frac{\log^+ |f^n(z)|}{d^n} - \log^+ |z| \right| \leq \frac{C}{d-1}$. As $|z| \rightarrow \infty$, $\log^+ |z| = \log |z|$, and so we have 2 by uniform convergence.

For property 3, since $|f^n(z)|$ is bounded (independently of n) for $z \in K(f)$, $G_f(z) = 0$.

Property 4 is immediate from the definition.

For $z \notin K(f)$, we can choose a small disc $U \ni z$ with compact closure in the basin of ∞ . So there is $m \gg 1$ such that $|f^n(U)| \geq 1$ for all $n \geq m$. So we can define a holomorphic logarithm of $f^n|_U$ for $n \geq m$, so that $\frac{\log^+ |f^n(z)|}{d^n}$ is harmonic on U . So G_f is a uniform limit of harmonic functions on U , and is harmonic on U .

For uniqueness, if $H(z)$ satisfies 1, 2, and 4, consider $G(z) := G_f(z) - H(z)$. G is continuous on $\widehat{\mathbb{C}}$, is bounded (by 2), and satisfies $G(f^n(z)) = d^n G(z)$. So as $n \rightarrow \infty$, $d^n G(z)$ is bounded, and so $G(z) = 0$, and hence $H = G_f$.

The final part follows as $\log |\phi_f(z)|$ satisfies 1, 2, 4. □

Remarks: G_f is also known as the **potential function** associated to $K(f)$, and one can use potential theory to show that $K(f)$ uniquely determines G_f .

From number theory, if $f(x) \in \mathbb{Q}[x]$ and $z \in \mathbb{Q}$, then all iterates of z are rational, and \mathbb{Q} comes equipped with a p -adic metric/norm, for primes p . One could (and some do) consider

$$G_{f,p}(z) = \lim_{n \rightarrow \infty} \frac{\log^+ |f^n(z)|_p}{d^n}.$$

Example: If $f(z) = z^d$, $d \geq 2$, then $f^n(z) = z^{d^n}$, and so

$$G_f(z) = \lim_{n \rightarrow \infty} \frac{\log^+ |f^n(z)|}{d^n} = \log^+ |z|$$

Theorem 8.15. Suppose $f(0) = 0$ is a superattracting fixed point with Böttcher coordinate ϕ for f at 0. There exists a unique open disc \mathbb{D}_r of maximal radius $0 < r \leq 1$ so that the inverse ψ of ϕ extends

holomorphically to $\psi : \mathbb{D}(0, r) \rightarrow \mathcal{A}_0$, where \mathcal{A}_0 is the immediate basin of the superattractor. If $r = 1$, then ψ maps the unit disk isomorphically onto \mathcal{A}_0 , and 0 is the only critical point in the immediate basin. If $r < 1$, then there is at least one other critical point in \mathcal{A}_0 , lying on the boundary of $\psi(\mathbb{D}(0, r))$.

Corollary 8.16. Let $f_c(z) = z^2 + c$, with $c \notin M$. Then c is the basin of ∞ , and the Böttcher coordinate extends to a neighbourhood of c .

Proof. Let $M = \{c \in \mathbb{C} : |f_c^n(0)| \not\rightarrow \infty \text{ as } n \rightarrow \infty\}$, and so $c \in M \implies 0 \in B(\infty)$. So $c = f_c(0) = 0^2 + c \in B(\infty)$, and $|\phi|(c) = |\phi|(f_c(0)) = |\phi|(0)^2$, where $|\phi|$ is the extension of the Böttcher modulus. In particular, $|\phi|(c) > |\phi|(0)$, since everything is mapped by $|\phi|$ outside \mathbb{D} , and so c is in the Böttcher domain. \square

9 Connectedness of the Julia set

Proposition 9.1. A closed subset of the sphere is connected if and only if every component of its complement is simply connected.

Proof. Suppose S is closed in $\widehat{\mathbb{C}}$, and S is disconnected, with $U \sqcup V$ an open disjoint cover of S . Define $S_1 = S \cap U^c$, $S_2 = S \cap V^c$. These are disjoint, closed (hence compact) subsets of $\widehat{\mathbb{C}}$, and so are a positive distance $\delta > 0$ apart. Take the boundary of a net of $\delta/3$ diameter squares which cover any component of S_1 , and smooth at the corners to obtain a Jordan curve $\gamma \subseteq \widehat{\mathbb{C}} \setminus S$ so that $\widehat{\mathbb{C}} \setminus \gamma$ has a component intersecting S_1 , and another component intersecting S_2 . So γ is not contractible, and hence S^c is not simply connected.

If $\widehat{\mathbb{C}} \setminus S$ is not simply connected with a nontrivial loop γ , then $\widehat{\mathbb{C}} \setminus \gamma$ has two components both intersecting S , and these disconnect S . \square

Proposition 9.2. Let f be a polynomial of degree $d \geq 2$. If all the finite critical points of f are contained in $K(f)$, then both $K(f)$ and $J(f)$ are connected. If at least one critical point belongs to the basin of infinity, then both $K(f)$ and $J(f)$ are disconnected.

Proof. If no finite critical points are in $B(\infty)$, then by the preceding theorem, the Böttcher coordinate extends to a conformal isomorphism $\phi : \widehat{\mathbb{C}} \setminus K(f) \rightarrow \widehat{\mathbb{C}} \setminus \mathbb{D}$, and so $\widehat{\mathbb{C}} \setminus K(f)$ is conformally a disc, and so simply connected. So by the preceding proposition, $K(f)$ is connected.

To show $J(f)$ is connected, consider any bounded Fatou component of f - call it U - and a simple closed curve γ in U . The bounded component V of $\widehat{\mathbb{C}} \setminus \gamma$ consists of points which do not go to infinity under iteration by the maximum modulus principle, since $B(\infty) \cap U = \emptyset$.

Since $J(f) = \partial B(\infty)$, $J(f) \cap V = \emptyset$. So $V \subseteq F(f)$, and hence $V \subseteq U$. Hence γ is contractible in U , and so U is simply connected, and $J(f)$ is connected.

Suppose now that $J(f)$ is connected, so $K(f)$ is too. Then $B(\infty) = \widehat{\mathbb{C}} \setminus K(f)$ is simply connected, and hence a hyperbolic simply connected domain, so by uniformization, conformally a disc. So this basin has Euler characteristic 1, and by Riemann-Hurwitz on $f|_{B(\infty)} : B(\infty) \rightarrow B(\infty)$, we have

$$\chi(B(\infty)) = (\deg f|_{B(\infty)})\chi(B(\infty)) - \sum_{p \in B(\infty)} (e_p - 1)$$

Substituting, this gives

$$\sum_{p \in B(\infty)} (e_p - 1) = d - 1$$

At $p = \infty$, we have $e_p = \deg f = d$, and so there are no other critical points, and $e_p = 1$ for all $p \in B(\infty) \setminus \{\infty\}$. \square

Corollary 9.3. *A parameter $c \in M$ if and only if the corresponding Julia set $J(f_c)$ is connected.*

Proof.

$$\begin{aligned} c \in M &\iff 0 \notin B(\infty) \text{ for } f_c \\ &\iff 0 \in K(f_c) \\ &\iff \text{all finite critical points of } f_c \text{ are in } K(f_c) \\ &\iff K(f_c), J(f_c) \text{ are connected} \end{aligned}$$

\square

To summarize, we have two definitions of the Mandelbrot set M :

$$M = \{c \in \mathbb{C} : J(f_c) \text{ connected}\} = \{c \in \mathbb{C} : |f_c^n(0)| \not\rightarrow \infty \text{ as } n \rightarrow \infty\}$$

Theorem 9.4. *The Mandelbrot set M is connected.*

Proof. Claim: Let $c \in \mathbb{C} \setminus M$. Then the Böttcher coordinate at ∞ takes the form $\phi_c(z) = z \prod_{n \geq 0} \left(1 + \frac{c}{f_c^n(z)^2}\right)^{1/2^{n+1}}$, and is conformal on a neighbourhood of c .

To see this, we need to check that $\phi_c(\infty) = \infty$ and $\phi_c(z)^2 = \phi_c(f_c(z))$ on a neighbourhood of c , and well defined.

$\phi_c(\infty) = \infty$ is clear.

$$\phi_c(z)^2 = z^2 \prod_{n \geq 0} \left(1 + \frac{c}{f_c^n(z)^2}\right)^{1/2^n} = z^2 \left(1 + \frac{c}{z^2}\right) \prod_{n \geq 0} \left(1 + \frac{c}{f_c^{n+1}(z)^2}\right)^{1/2^{n+1}}.$$

$$\phi_c(f_c(z)) = f_c(z) \prod_{n \geq 0} \left(1 + \frac{c}{f_c^{n+1}(z)^2}\right)^{1/2^{n+1}}.$$

Since $f_c(z) = z^2 + c$, these two expressions agree.

For convergence on a neighbourhood of c , recall that $c \notin M \implies$ there is a neighbourhood U_c such that the domain of conformality for ϕ_c contains c . Notice that ϕ_c converges on a neighbourhood of c if $\log \phi_c$ is holomorphic on a neighbourhood of c , i.e. if $\log z + \sum_{n \geq 0} \frac{1}{2^{n+1}} \log \left(1 + \frac{c}{f_c^n(z)^2}\right)$ is holomorphic on a neighbourhood of c .

Since $c \notin M$, $c \notin K_{f_c}$, and there is a fixed iterate N such that, for all $n > N$, $|f_c^n(z)| > |f_c^{n-1}(z)|$ for all z on a small neighbourhood of c . This holds because

$$|G_{f_c}(z) - \log |z|| \leq \frac{C}{d-1} \leq \log \left|1 + \frac{c}{z^2}\right| \approx 0 \text{ if } |z| \gg 1$$

In fact, we see that this N provides the same uniformity for all c' close to c . In particular

$$\phi_c(c) = c \prod_{n \geq 0} \left(1 + \frac{c}{f_c^n(c)^2}\right)^{1/2^{n+1}}$$

converges uniformly on compact subsets of $\mathbb{C} \setminus M$.

We give this a name: define $\Phi : \mathbb{C} \setminus M \rightarrow \mathbb{C} \setminus \bar{\mathbb{D}}$ by $\Phi(c) := \phi_c(c)$. We've shown that Φ is holomorphic.

$$\frac{\Phi(c)}{c} = \prod_{n \geq 0} \left(1 + \frac{c}{f_c^n(c)^2}\right)^{1/2^{n+1}} \rightarrow 1 \text{ as } |c| \rightarrow \infty$$

So Φ has a removable singularity at ∞ , and $\Phi(\infty) = \infty$.

Claim: $\Phi : \widehat{\mathbb{C}} \setminus M \xrightarrow{\sim} \widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}$.

1. Φ is proper: if not, then there is a compact $K \subseteq \widehat{\mathbb{C}} \setminus \bar{\mathbb{D}}$ such that $\Phi^{-1}(K)$ is not compact in $\widehat{\mathbb{C}} \setminus M$, i.e. has a subsequence approaching ∂M - call it $\{c_n\}$ converging to $c_0 \in \partial M$. Then $|\phi_{c_n}(c_n)| \geq 1 + \varepsilon$ for some $\varepsilon > 0$, by compactness.

Since $c_0 \in \partial M$, $G_{f_{c_0}}(c_0) = 0$, and for any $\varepsilon > 0$ and $N \in \mathbb{N}$ there is some $\delta > 0$ with

$$|c - c_0| < \delta \implies |f_c^N(c) - f_{c_0}^N(c_0)| < \varepsilon$$

If $B \gg 1$, sufficiently large that near c_0 ,

$$|G_{f_c}(z) - \log |z|| \leq \log \left|1 + \frac{c}{z^2}\right|$$

is very small for $|z| \geq B$, then we can find, for $c \notin M$ some N with:

$$|\phi_c(c)|^{d^{N-1}} \leq B < |\phi_c(c)|^{d^N}$$

This choice of N is constant on a small neighbourhood of such c .

But, for any fixed N , we cannot have $|f_c^N(c)| \geq B$ on the neighbourhood of radius δ about c_0 , so this value of $N \rightarrow \infty$ as $c \rightarrow c_0$, i.e. $\log |\phi_c(c)| \rightarrow 0$ as $c \rightarrow c_0$, contradicting $|\phi_c(c)| \geq 1 + \varepsilon$. Thus the map is proper and has well-defined degree.

2. Since $\Phi^{-1}(\infty) = \{\infty\}$ with degree 1 since $\Phi(c)/c \rightarrow 1$ as $|c| \rightarrow \infty$, we have a conformal isomorphism.

So $\widehat{\mathbb{C}} \setminus M \cong \widehat{\mathbb{C}} \setminus \bar{\mathbb{D}} \cong \mathbb{D}$, so $\widehat{\mathbb{C}} \setminus M$ is simply connected, and thus M is connected. \square

Note that in the proof of Koenig's linearization theorem, we only needed $|\lambda| \neq 0, 1$. We've only used these linearizations for attracting fixed points, but this gives Koenig maps for repelling cycles.

If z_0 is fixed f and $f'(z_0) = \lambda$ of modulus $|\lambda| > 1$, then if z is in the neighbourhood where linearization holds, and $z \in J(f)$ - such a z exists because $z_0 \in J(f)$ and there are no isolated points in $J(f)$ - then $\phi^{-1}(\{\lambda^n \phi(z) : n \in \mathbb{N}\}) \subseteq J(f)$. If $\lambda \notin \mathbb{R}$, then $\lambda^{-n} \phi(z)$ limits to a spiral at 0. This explains to a certain extent why we often get Julia sets that look like spirals.

Corollary 9.5. Suppose z_0 is a repelling fixed point for the rational map f . Then there is a holomorphic map $\psi : \mathbb{C} \rightarrow \widehat{\mathbb{C}}$ with $\psi(0) = z_0$, so that the diagram

$$\begin{array}{ccc} S & \xrightarrow{f} & S \\ \psi \uparrow & & \uparrow \phi \\ \mathbb{C} & \xrightarrow{\cdot \lambda} & \mathbb{C} \end{array}$$

commutes, with ψ holomorphic on a neighbourhood of 0. ψ is unique up to precomposition with a scaling, that is $w \mapsto \psi(cw)$ for $c \neq 0$.

Proof. We know by Koenig that ψ exists on a neighbourhood of 0 - call it U . Given $w \in \mathbb{C}$, there is $n \gg 1$ such that $\frac{w}{\lambda^n} \in U$. Define $\psi(w) := f^n(\psi(w/\lambda^n))$, and check the rest. \square

10 Parabolic Fixed Points

An indifferent periodic point of a rational map f is said to be **parabolic** if λ is a root of unity.

Recall that we have already shown that all parabolic points are in $J(f)$, so there is no linearization on a neighbourhood.

For example, consider $z \mapsto z + z^2$ at 0, and $z \mapsto z + 1$ at ∞ . Looking at the behaviour on the real axis, on one side we move in towards the fixed point, whilst on the other side we are repelled away.

We will focus for now on the case $\lambda = 1$, with a fixed point at 0.

We can write $f(z) = z + az^{n+1} + \dots = z(1 + az^n + \dots)$.

In this setting, let v'_0 be any complex number such that $nav'_0 = 1$, and define the vector v_0 to be the vector $0\vec{v}'_0$. For $k \in \{1, \dots, 2n-1\}$, define $v_k := e^{\pi i k/n} v_0$.

The **repelling vectors** for the parabolic fixed point are $v_0, v_2, \dots, v_{2n-2}$ and the **attracting vectors** are $v_1, v_3, \dots, v_{2n-1}$.

We call n the **multiplicity** of the parabolic fixed point, and write $c := -\frac{1}{na}$, and

$$\Delta_j := \left\{ r e^{i\theta} v_j : r > 0, |\theta| < \frac{\pi}{n} \right\}$$

Then $\phi(z) := \frac{c}{z^n}$ maps Δ_j biholomorphically onto $\mathbb{C} \setminus \mathbb{R}_{\geq 0}$ if j is even, and $\mathbb{C} \setminus \mathbb{R}_{\leq 0}$ if j is odd.

We have for each j an inverse $\psi_j : \mathbb{C} \setminus \mathbb{R}_{\pm} \Delta_j$ to ϕ .

Now write $F_j(z) = \phi \circ f \circ \psi_j$. We have

$$f \circ \psi_j(w) = \left(\frac{a}{w} \right)^{1/n} \left(1 + \frac{ac}{w} + o\left(\frac{1}{w} \right) \right) \text{ as } |w| \rightarrow \infty$$

And so

$$F_j(z) = w \left(1 + \frac{ac}{w} + o\left(\frac{1}{w} \right) \right)^{-n} = w \left(1 - \frac{nac}{w} + o\left(\frac{1}{w} \right) \right)$$

Now, since $c = -\frac{1}{na}$, $F_j(w) = w + 1 + o(1)$ as $|w| \rightarrow \infty$.

Choose $R > 0$ such that, for all $0 \leq j \leq 2n - 1$ we have

$$|F_j(w) - w - 1| < \frac{1}{2}$$

for $|w| > R$.

Then $\Re(F_j(w)) > \Re(w) + \frac{1}{2}$, so if $z = \psi_j(w)$ is sufficiently small, then

$$\Re(\phi(f(z))) > \Re(\phi(z)) + \frac{1}{2}$$

If j is odd, so $\psi_j(\Delta_j) = \mathbb{C} \setminus \mathbb{R}_{\leq 0}$, the right half plane $\mathbb{H}_R := \{w \in \mathbb{C} : \Re(w) > R\}$ maps to itself under F_j , so f maps $\psi_j(\mathbb{H}_R)$ to itself, and the iterates $f^k|_{\psi_j(\mathbb{H}_R)}$ converge uniformly to 0. This image $\psi_j(\mathbb{H}_R)$ is known as an **attracting petal** for f , and is Fatou.

If j is even, then we have $\psi_j(\{w : \Re(w) < R\})$ cannot map to itself, but describes a region on which dynamics behave like $w \mapsto w + 1$ on a neighbourhood of $\mathbb{R}_{<0}$. $\psi_j(\{w : \Re(w) < R\})$ is a **repelling petal** for f .

Note that any point attracted to 0 under iteration must come in along an attracting vector, because eventually its orbit must contain points close to 0, not on a repelling vector. So we can use one of these F_j s to study the dynamics. We have for $|z| \ll 1$ that $\Re(\phi(f(z))) > \Re(\phi(z)) + \frac{1}{2}$, so we do lie in an attracting petal associated to an attracting vector for a sufficiently large iterate f^n of z . Write $w_k := \phi(f^k(z))$ for this point z , then $\Re w_k \rightarrow \infty$ and $w_{k+1} - w_k \rightarrow 1$ as $k \rightarrow \infty$. So $\frac{w_k - w_0}{k} \rightarrow 1$, and hence $w_k \approx k$ as $k \rightarrow \infty$, i.e. $f^k(z) \approx v_j$ as $k \rightarrow \infty$, where $\psi_j(\mathbb{H}_R)$ is the petal for v_j .

If v is an attracting vector associated to a parabolic fixed point with multiplier 1, then the **basin of attraction** associated to v is the set of points attracted to the fixed point from the direction of v .

The basin of attraction for the point is the union of these.

11 General Parabolics

Definition 11.1. Let v be an attracting vector for a fixed point of multiplier 1. Then the **parabolic basin of attraction associated to v** is the set of points converging to the parabolic point from direction v , and the **immediate basin associated to v** the Fatou component containing v . If $\lambda^q = 1$, we use the same terminology, for f^q . The **parabolic basin of attraction** is the union of all such vector-associated basins.

Lemma 11.2. Let $\lambda = e^{2\pi i p/q}$ be a primitive q^{th} root of unity, and $f(0) = 0$ with multiplier λ . Then the multiplicity of 0 as a fixed point of f^q is congruent to 1 mod q .

Proof. Let $n + 1$ be the multiplicity of 0 as a fixed point of f^q . If $z_0 \mapsto f^q(z_0) \mapsto f^{2q}(z_0)$ is attracted to 0 along vector v , then $f(z_0) \mapsto f^{q+1}(z_0) \mapsto f^{2q+1}(z_0)$ is attracting to 0 along vector λv . In other words, multiplication by λ permutes the n attracting vectors, and so $n \equiv 0 \pmod{q}$, and so $n + 1 \equiv 1 \pmod{q}$. \square

Theorem 11.3. Suppose \mathcal{P} is an attracting basin of f for the parabolic fixed point z_0 . Then there exists a conformal embedding $\alpha : \mathcal{P} \rightarrow \mathbb{C}$, unique up to composition with a translation, such that

$$\alpha(f(z)) = 1 + \alpha(z)$$

for all $\alpha \in \mathcal{P} \cap f^{-1}(\mathcal{P})$. This map extends uniquely to a map $\mathcal{A} \rightarrow \mathbb{C}$ on the attracting basin for the parabolic point, which necessarily contains a critical point of f .

We won't prove this here, but we will prove that there is a critical point in the basin of attraction of a parabolic fixed point.

Proof. Translate so that 0 is the parabolic fixed point. Replace f by an iterate to assume $f'(0) = 1$, noting the basin remains unchanged. Consider the sectors associated to attracting vectors D_0 , with $f(D_0) \subseteq D_0$, with edges E_+, E_- in the positive and negative direction from the attractor:

If there's no critical points of f in the basin of attraction for 0, we can define a branch $f^{-n} : D_0 \rightarrow D_n$, with $D_0 \subseteq D_n$. By definition, each $D_n \subseteq$ basin of attraction of 0, which is hyperbolic, so the collection $\{f^{-n}|_{D_0}\}$ form a normal family by Montel's theorem. So there is some subsequence n_k with f^{-n_k} converging to a holomorphic limit on D_0 .

One can compute analytically that the only such possible limit is the constant function 0. For $k \gg 1$, $|f^{-n_k}(K)| \ll 0$ for compact $K \subseteq D_0$, contradicting $D_0 \subsetneq D_1 \subsetneq \dots$

Hence there must be a critical point in the basin as claimed. \square

Corollary 11.4. *Let f be a rational map of degree $d \geq 2$. Then f has at most $4d - 4$ non-repelling cycle.*

Proof. Suppose f has $\geq N$ indifferent cycles and $\geq M$ attracting cycles. Consider for $t \in \mathbb{C}$ the map $f_t(z) := (1 - t)f(z) + tz^d$. For an indifferent cycle of f of period k containing a point α , we may analytically continue $t \mapsto \alpha(t)$ as a holomorphic function from a neighbourhood of 0 to a period n point for f_t by the implicit function theorem, so long as α is not a repeated root of $f^n(z) - z$. This occurs only if $\lambda = 1$, and in this case, replace $t = u^s$ for some s to draw the same conclusion.

We then have a holomorphic multiplier map $t \mapsto \lambda(t)$, where $\lambda(t)$ is the multiplier of $\alpha(t)$ for f_t . If λ is constant, it is either equal to 1 constantly, or we can extend α, λ throughout \mathbb{C} . When $t = 1$, $f_t(z) = z^d$, which has no indifferent cycles, and so we have a contradiction if $\lambda(t)$ is constant but not 1.

Denote $N_1 = \{\text{indifferent cycles with } \lambda(t) = 1\}$, and N_2 the other indifferent cycles.

Then consider the set $\{\theta \in [0, 2\pi) : |\lambda(\varepsilon e^{i\theta})| < 1\}$. Since λ is conformal for cycles in N_2 , this set has measure $\frac{1}{2}$. So for any cycle in N_2 , a measure $\rightarrow \frac{1}{2}$ set of perturbations of $t = 0$ of size ε make

the cycle attracting. Repeating this for all cycles in N_2 , we may find a perturbation direction so that at least $|N_2|/2$ of the cycles in N_2 become attracting.

So we have $t \in \mathbb{D}^\times$ such that f_t has $\geq |N_1|$ parabolic cycles, and $\geq \frac{|N_2|}{2} + M$ attracting cycles. So, since these all must attract some critical point, $|N_1| + \frac{|N_2|}{2} + M \leq 2d - 2$, as f_t is of degree d also.

So $N + M \leq 4d - 4$. □
